Process and Apparatus for Minimizing Thermal Gradients Across an Advanced Lithographic Mask

Background of the Invention

[0001]   Field of the Invention

[0002]   This invention relates to advanced lithographic masks. Particularly, it relates to projection lithography employing soft x-ray radiation or extreme ultraviolet (EUV) radiation and, more particularly, to methods and systems that provide for the reduction of thermal gradients on extreme ultraviolet lithography (EUVL) reticles during scanning.

[0003]   Background of the Invention

[0004]   Extreme ultraviolet lithography is a leading candidate for the production of integrated circuits with feature sizes of 65 nm and below. EUVL is different from other lithographic technologies in that it is based on reflective lithographic technologies when compared to conventional transmissive optical lithography. In a simplified description of this technology, a patterned EUVL mask is exposed to EUV or soft x-ray radiation and the corresponding pattern is eventually reflected rather than transmitted onto a resist coated substrate, where the resist is exposed and the desired pattern is formed.

[0005]   An EUVL mask consists of an absorbing film deposited on a multilayer reflective coating which is deposited on a substrate. Additional films such as a buffer layer or etch stop layer can be deposited between the multilayer stack and absorber film to aid

in certain aspects of the mask manufacturing process if desired. The substrate is typically a material that has very low thermal expansion characteristics. The multilayer reflective coating is a Bragg mirror consisting of 40 bilayers of silicon and molybdenum. The use of silicon and molybdenum as the bilayers is specifically optimized for a peak EUV reflectivity wavelength of 13.4 nm. Other combinations, such as beryllium and silicon, can be used as well, although the peak reflectivity wavelength may differ. The absorber film is any element, compound, or alloy, such as chrome or tantalum nitride, deposited at a thickness such that over 99% of the EUV radiation is absorbed. To create a patterned mask, the absorber layer, as well as any underlying layers between the multilayer stack and absorber layer, are removed in specific areas by known manufacturing processes to create a desired pattern. Where the absorber and underlying layers are removed (the patterned area), the EUV radiation is reflected by the multilayer stack. Where the absorber remains (the unpatterned area), the EUV radiation is absorbed.

[0006]   The entire mask is not exposed all at once, but the EUVL reticle is scanned across a segment of EUV radiation which exposes only a small portion of the mask, leaving the remainder of the mask unexposed. The radiation exposes both patterned and unpatterned areas.

[0007]   The absorption of the radiation in the unpatterned areas can lead to noticeable temperature gradients on areas of the mask, which can produce mask distortion due to thermal expansion and consequently image size and placement errors. Modeling results from the University of Wisconsin have shown that thermal gradients of up to 1.9Â°C can exist across an EUV mask during continuous exposure. For individual points on the mask, the simulation results indicated that temperature variations up 0.48Â°C can exist due to the localized heating and cooling during the exposure. These results also indicated that in-plane displacements (IPD) can be up to 1.33 nm. Magnification correction has been shown to reduce the IPD's. However, the cyclic heating and cooling during the exposure reduced its effectiveness as did changes in the pattern density. After magnification correction, the maximum IPD was simulated to be 0.6 nm. (See C. Martin, R. Englestad, E. Lovell, "Thermomechanical Modelling of an EUV Reticle During Exposure," Computational Mechanics Center, University of Wisconsin – Madison, March 7, 2001.) Since these are simulation results, the trends of

the results are more important rather than the actual numbers. Because the simulations are based on ideal assumptions and conditions, the actual values are expected to be somewhat higher.

[0008]   Others have identified thermal gradients as a problem for EUV mask operation and have tried to solve it using substrate cooling or heating systems or processes. For example, European Patent Application EP 1 120 690 A2 and U.S. Patent 6,098,408 issued to Levinson et al. provide such processes. These methods, however, can not account for various pattern densities across a mask. Others have attempted to solve this problem by selective placement or omission of coating on the reticle, for example , U.S. Patent No. 6,316,150 issued to Gianoulakis et al.

Brief Summary of the Invention

[0009]   To solve the problem of thermal gradient distortion during EUV exposure, an additional heating source is used to heat the areas where the EUV radiation is not exposing the mask. A filter or filters are used to control which part or parts of the reticle receive this additional radiation. This effectively minimizes any thermal gradients across the mask by supplying a constant heat flux to the entire surface of the mask, creating more of a predictable and controllable steady state operation. This can also be used to minimize any transient effects due to start-up or pauses for wafer changes. With minimal or no thermal gradients across the mask, image placement and size errors can be reduced significantly or at least reduced enough so that magnification correction can be effective. To control the mask from overheating, a heat sink may have to be used to remove the added heat from the mask (these techniques are well known).

Brief Description of the Several Views of the Drawings

[0010]   FIG. 1 illustrates a typical way in which an EUVL reticle is exposed to EUV radiation.

[0011]   FIG. 2 illustrates schematically how the invention is intended to solve the problem of thermal gradients on EUV reticle.

[0012]   FIG. 3 illustrates from a system standpoint how the invention would operate in an EUV lithography environment.

[0013]   FIG. 4a illustrates graphically the density patterns of an example EUV mask.

[0014]   FIG. 4b illustrates graphically how the filter for the heat radiation is patterned to complement the density pattern of the mask.

[0015]   FIG. 5 illustrates in schematic form the heat source moving with the reticle.

[0016]

$$H = mC_p(T_2 - T_1)$$

[0017]   FIG. 6 illustrates in schematic form the heat source rotating to follow the reticle movement.

[0018]   FIG. 7 illustrates in schematic form larger filters that use liquid crystal technology to create the moving pattern while the actual source remains stationary.

Detailed Description of the Invention

[0019]   FIG. 1 illustrates a typical way an EUVL reticle is exposed to EUV radiation. For most systems reticle 12 is moved across the field exposed by the projection optics. As the EUV reticle surface is scanned across the EUV exposure field , areas are created where the reticle is exposed to EUV radiation and areas that are not exposed to EUV radiation, creating localized heating (areas 10 exposed to EUV radiation) and cooling (areas 14 not exposed to EUV radiation) phenomenon. This causes temperature gradients across the mask, which can ultimately affect image size and placement due to thermal expansion of the mask substrate. To mitigate these image size and placement errors, the thermal gradient between areas 10 and 14 needs to be minimized. Since area 10 is receiving heat from the EUV radiation from the lithography process, the other areas of the EUV reticle designated by 14 are the proposed areas for the additional heat source. As illustrated, the section of the mask exposed to radiation 10 and the areas 14 that are not exposed vary as a function of time as the reticle is moved across the EUV exposure field.

[0020]   FIG. 2 illustrates schematically how the invention is intended to solve the problem of thermal gradients on EUV reticle. By supplying an additional heat source 20 to the areas of the mask that aren't exposed to EUV radiation, a constant heat flux can be

supplied to the mask surface, minimizing any temperature gradients across the mask surface. This is done through one or more filters, illustrated as Filter A and Filter B in FIG.2.

[0021]   FIG. 3 illustrates an example system how the invention would operate in an EUV lithography environment. As the EUVL reticle 12 is scanned across the EUV exposure field, additional heat through heating source 20 will be supplied to the non-EUV exposed areas (14 in FIG. 1) through optics 34 and Filters A and B in such a manner to maintain the surface of the mask at a constant temperature. Control device 32 both measures temperatures and controls cooling chuck 31 and heating source 21. It also synchronizes Filters A and B with the movement of the EUVL reticle 12 on reticle stage 33.

[0022]   Calculations in table 1 below indicate that a 200W heating source is adequate to maintain the reticle at a constant temperature. The calculations are based on crystalline and elemental densities and specific heat capacities, so the actual numbers may be somewhat lower. The calculations are based on the heat needed to raise the temperature of the EUVL reticle 1.9Â°C in 50 seconds (shown by the University of Wisconsin to be the cycle time for the minimum and maximum temperatures due to heating and cooling during the exposure time). The total amount of heat needed was calculated using the basic formula: $H=mC_p(T_2-T_1)$ and summing the heat over all of the layers and the substrate where H is the enthalpy of the material, m is the mass of the material, C_p is the specific heat capacity of the material, and T_1 and T_2 are the minimum and maximum temperatures of the material, respectively. According to Kirchhoff's Law, the emissivity and absorptivity of a given surface are equal at the same temperature. The absorptivity is simply the fraction of radiation that is absorbed from an external source. Consequently, the source heat needed is simply obtained by dividing the energy required to raise reticle 1.9Â°C in 50 seconds by the absorptivity. In this case, the absorptivity of polished chrome was used. Most other materials have a larger absorptivity than polished chrome, which would correspondingly result in a lower amount of heat necessary to maintain the temperature.

[0023]   Table 1 – Example Calculations to Determine the Additional Heating Source Energy

[0024]   .

[t1]

Absorber Specific Heat Capacity (Cr):	0.449 J/gK
Absorber Density (Cr):	7.190 g/cm^3
Absorber Thickness (Cr):	1.000E-07 m
Buffer Layer Specific Heat Capacity (SiO$_2$):	0.959 J/g K
Buffer Layer Density (SiO$_2$):	2.600 g/cm^3
Buffer Layer Thickness (SiO$_2$):	8.000E-08 m
Multi Layer Specific Heat Capacity (Si):	0.7095 J/g K
Multi Layer Specific Heat Capacity (Mo):	0.2472 J/g K
Multi Layer Density (Si):	2.340 g/cm^3
Multi Layer Density (Mo):	10.200 g/cm^3
Multi Layer Thickness (Si):	1.393E-07 m
Multi Layer Thickness (Mo):	1.427E-07 m
Substrate Specific Heat Capacity (SiO$_2$):	0.959 J/g K
Substrate Density (SiO$_2$):	2.600 g/cm^3
Substrate Thickness (SiO$_2$):	6.350E-03 m
Differential Temperature:	1.9 °C
Exposure Time:	50 sec
Plate Area:	0.0232 m^2
Absorbtivity (polished chrome @T=20°C):	0.075
Energy Needed to be Absorbed by Absorber:	0.00028 W
Energy Needed to be Absorbed by Buffer:	0.00018 W
Energy Needed to be Absorbed by Multilayer:	0.00032 W
Energy Needed to be Absorbed by Substrate:	13.9740 W
TOTAL ENERGY NEEDED TO BE ABSORBED:	13.9747 W
SOURCE ENERGY NEEDED:	186.3 W

[0025]   The additional radiation for the non-EUV radiated areas will be at a wavelength and intensity that will effectively maintain a constant temperature across the surface of the mask when compared to the EUV radiated areas.

[0026]   The purpose of Filter B in FIG. 3 is to define a complimentary pattern to the EUV mask. Where the EUV mask is densely patterned (less absorber), the complimentary mask would be patterned lightly, letting more radiation through the complementary mask. Where the EUV mask is lightly patterned (more absorber), the complementary mask would have a denser pattern, restricting the radiation passing through it. In this manner, the densely patterned areas on the EUV mask would receive more heat than the lightly patterned area which would minimize any thermal gradients across the EUV mask due to different pattern densities. An example of a patterned mask and its complementary filter are illustrated in FIGS. 4a and 4b respectively. This filter could be something as simple as a chrome on glass optical mask or something more complex

like a liquid crystal filter, which are akin to LCDs' used in projection TV systems.

[0027] The purpose of Filter A is to provide the pattern of the illumination strip. The illumination strip is the actual EUV light that the EUVL mask is scanned across. Depending on the exposure system design, the pattern in this filter may or may not need the capability to move with the EUVL reticle and/or EUV illumination strip. The width and speed of this complimentary illumination pattern can be control variables. A liquid crystal filter would be adequate for this purpose.

[0028] Filter A or B can also be used to control the wavelength of light that passes to the EUVL reticle. This may be necessary during the transient start-up phase or mask preheat cycle, which would allow a different wavelength and or intensity of light that is transmitted to the reticle surface to achieve optimal heating results. This also may be necessary for extended exposure times. This can be done using filter technology such as acousto-optical filter and/or liquid crystal filters. This function of controlling the wavelength could just as easily be combined with Filter B providing that Filter B is an LCD filter. Further, these filters can be combined into one filter using LCD technology. This greatly simplifies the optical alignment of the system as well as reduce the overall cost of the heating system. However, this may complicate the control strategy. [0029]
FIGS. 5-7 are different configurations for the heat source and Filters A and B to account for the moving reticle. The EUV light source is rather difficult to illustrate in these drawings since they are two dimensional. So the figures do not show the EUV

light. However, in three dimensional terms if the EUV light is in the X-Z plane, then the heating source would be in the Y-Z plane. In all of these cases, Filter A or the pattern in Filter A may or may not move.

[0030]   FIG. 5 illustrates in schematic form the heat source moving with the reticle. The pattern in Filter A or Filter A itself may not have to move at all since its function is to account for the stationary EUV illumination strip of the system.

[0031]   FIG. 6 illustrates in schematic form the heat source rotating to follow the reticle movement.

[0032]   FIG. 7 illustrates in schematic form larger Filters A and B that uses liquid crystal or like technologies to create the moving pattern while the actual source 20 remains stationary. Similar to above, the pattern for Filter A may not have to move at all since its function is to account for the stationary EUV illumination strip.

[0033]   Although only preferred embodiments of the invention are specifically disclosed and described above, it will be appreciated that many modifications and variations of the present invention are possible in light of the above teachings and within the purview of the appended claims without departing from the spirit and intended scope of the invention. For example, instead of the reticle table moving as shown herein it is possible that the EUV illumination optics could move. Other variations could occur with the type of filters, number of filters, orientation of the heat source and other environmental conditions without departing from the spirit and claims of the invention. Also, this invention could apply to other lithography systems where such thermal gradient distortion may take place. For example, thermal distortion gradients may appear at the 157 nanometer level, as well.
